INTRODUCTION

Fresno Dam and Reservoir is located on the Milk River about 13 miles upstream or west of Havre in north-central Montana. Construction by the Bureau of Reclamation was completed in 1939. The original surface area of Fresno Reservoir in 1939 was 5,760 acres and the capacity was 129,062 acre-feet at the water surface elevation of 2575.0 feet. The 1978 survey resulted in a surface area of 4,878 acres and a capacity of 103,397 acre-feet at the same water surface elevation. Fresno reservoir is the principal storage component of the 124,200-acre Milk River Project. Location of the project features is shown on the project map (Figure 1). Figure 2 shows plan and section views of Fresno Dam.

The drainage area above Fresno Dam is 3,766 square miles, of which 3,096 square miles is the net sediment contributing area. Elevations range from slightly more than 2,500 feet near the dam to about 10,000 feet on the western fringe, but only a very small part of the area is higher than 5,000 feet.

The Milk River rises in the mountains of Glacier National Park and flows northeasterly into Canada. It then flows easterly more than 200 miles through the Province of Alberta and recrosses the International Boundary in northwestern Hill County, Montana, where it travels a southeasterly course to Fresno Reservoir. Below Fresno, the Milk River flows easterly and empties into the Missouri River below Fort Peck Reservoir in northeastern Montana. The western fringe of the drainage is mountainous, but the major part of the area ranges from steeply to gently rolling topography. Through the irrigation season, the flow of the Milk River above Fresno is augmented by water from the St. Mary River which flows into the Milk River via the St. Mary Canal. The St. Mary River water is diverted at a point below Lake Sherburne, near the boundary of Glacier National Park, and flows through the St. Mary Canal to the headwaters of the North Fork of the Milk River.

Sedimentation has long been recognized as a serious problem in the Milk River. Indeed, the river was named for the opaque appearance of its water. Bank sloughing and channel alteration have been observed along the entire length. The specific amount of sediment accumulation in Fresno Reservoir had not been determined prior to this resurvey, but it was known to be significant.

In the years immediately preceding the resurvey two events occurred to bring attention to the sedimentation problem. One was the claim initiated by the Canadian government that the additional flow of St. Mary River water in the Milk River had caused widespread bank erosion and accompanying loss of valuable farm land and improvements. The other was complaints of boaters at Fresno Reservoir running aground on sand bars or islands, even in the lower or deeper parts of the reservoir. It therefore became apparent that a reservoir resurvey was needed at Fresno Reservoir.

Both 1976 and 1977 were low runoff years and Fresno Reservoir was drawn down to nearly empty in mid-July 1977. The extreme drawdown presented an excellent opportunity for aerial photography for a resurvey. A contract was issued and aerial photography was performed in October

1977. The underwater measurements were made in the spring of 1978. Both parts of the fieldwork are discussed elsewhere in this report. Because the survey was completed in 1978, it is henceforth referred to as the 1978 resurvey.

The 1978 sediment resurvey was the first since Fresno Dam was completed in 1939. This report has been written to document the field survey methods and computational procedures used to obtain the elevation-area-capacity curves and tables presented in this report. Comparison of these curves with the original elevation-area-capacity curves is made to show the effects of over 38 years of sedimentation in Fresno Reservoir. Because sediment ranges were not established when the dam and reservoir were completed and the topography used for the original area-capacity tables could not be located, the extent of analysis that could be performed was limited.

SURVEY METHODS

Aerial Survey

When the decision to conduct a reservoir resurvey was made during the irrigation season of 1977, a number of actions were initiated. The sediment ranges were located on 1:24,000 ($7\frac{1}{2}$ -minute) quadrangle sheets by Regional and E&R Center personnel. Figure 3 is an index map for Figure 4 (sheets 1-4) that show the location of these sediment ranges. The sediment ranges were field located and control panels for aerial photography placed by surveyors from the Upper Missouri Projects Office. Horizontal and vertical control used for the sediment resurvey is shown in Table 1. A contract to conduct the aerial survey was awarded to Delta Aerial Surveys, Denver, Colorado.

The aerial photographs were taken in October 1977. Fieldwork to establish the horizontal and vertical coordinates of the control panels was continued in the winter and spring of 1978. After receiving the ground control data, the contractor measured the cross sections from the aerial photography. The data furnished by the contractor was in the form of punched cards which were ready for computation by automatic data processing.

Underwater Survey

The underwater portion of the reservoir resurvey was done by Bureau personnel in May and June 1978. Measurements of depth were made at Ranges 1 through 10, 40, 50, and 51. The remainder of the sediment ranges were either dry at the time of the aerial survey or were surveyed using conventional land surveying techniques.

The fieldwork for the underwater survey was performed in two sessions. In general, the first session was used to prepare for a smooth, efficient operation when the actual underwater measurements were made. This session was used to assemble and check out the equipment for the underwater measurements. The boat and Electronic Distance Measuring Device (EDMD) were operated for familiarization. The sediment range lines had been located and marked by field personnel prior to the aerial photography. Since these markers were located on the top of bluffs overlooking the reservoir, it was necessary to establish a point on line near the edge of the water for use as an instrument station when the underwater measurements were made.

The second session consisted of profiling the underwater portion of the sediment range lines. The water depths were measured with a boat-mounted depth sounding device that operates on the sonar principle. This instrument, supplied by the sedimentation section of the E&R Center, prints a continuous trace of depth as the boat travels across the water surface along the range line. A vertical line is drawn on the chart on command to mark distances, scales, etc. and handwritten notes may be entered on the chart to aid interpretation. Distances along the range line (offsets) were measured using an Electronic Distance Measuring Device (EDMD). The instrument used for the Fresno Reservoir resurvey was chosen because it could be operated in a dynamic or tracing mode

and also because it provided for voice communication between the stationary and mobile units, or, in this case, the shore station and the boat.

The procedure used in profiling the underwater portion of each line was as follows:

The stationary unit of the EDMD and a transit were located on the range line on the right bank and as close to the edge of water as practical. The flags set during the preliminary session were used for references. The distance along the range line (offset) to the edge of water was measured with a tape. The first few shallow underwater measurements were made by sounding with a level rod and the offset distances measured by tape from the reference flag. The boat containing the sounding gear and dynamic part of the EDMD was located on-line by transit and the EDMD and depth sounder turned on. With the electronic instruments functioning, the boat was set in motion and proceeded across the reservoir at a moderate rate. The boat was kept on-line by the transit operator communicating with the boat operator by voice through the EDMD. The EDMD operator on board the boat monitored the distance the boat traveled and informed the sounding operator to mark the chart at the appropriate points. When the boat reached the left bank, any needed shallow measurements were made by sounding with a rod and the distance to the left range marker measured by tape. This last distance measurement was made to check the distances read by the EDMD.

RESERVOIR AREA AND CAPACITY COMPUTATIONS

Data Preparation

As discussed previously, cross section data were obtained from two different sources, aerial photography and sonar readings, which were taken at different times. These data had to be combined to obtain complete cross sections. This combination of data was accomplished in the following manner.

At the time the aerial photography was done, October 1977, the water surface in Fresno Reservoir was at approximately 2547.0 feet. The following spring when the sonar readings were taken the water surface had risen to approximately 2570 feet. Because of this difference in water surface, offset and elevation data were obtained by both methods for approximately 23 vertical feet. This overlap of data offered a means to compare the data and insure that the data sets were indeed compatible. The cross section data taken by both methods were plotted to the same scale on separate sheets. Separate sheets were used because the field data were measured from different datums, or zero, for offsets and from opposite sides of the reservoir. The two plots for each range were superimposed or overlaid for comparison. In all cases, the slopes on both sides compared quite closely with only small variations in individual segments. The distances across the reservoir, as indicated by the two sets of data, varied slightly, generally 1 to 2 percent. These minor differences can be explained by the fact that the measurements may not have been taken on exactly the same line. It is also possible that the elevations determined from photographs taken when the soils were dry may differ slightly, due to shrink-swell factors, from those determined by sounding when the material was saturated. Since the differences were minor, the data were accepted. The data from the underwater survey were used to complete the cross sections at each sediment range.

Cross section data were provided between the sediment range lines at even 500-foot stations by the aerial survey contractor. The underwater portion of each intermediate cross section was completed graphically using the upstream and downstream ranges as a guide.

Plots of the complete sediment range cross sections are shown in Figures 5 through 52.

Elevation-Area-Capacity Computations from Cross Section Data

Cross section data were used to compute areas and volumes at 1-foot elevation increments. The computations were performed on a digital computer using Program 268, Elevation-Area-Capacity Tables, written by personnel of the Division of Data Processing, Mid-Pacific Region, Bureau of Reclamation, Sacramento, California. This program uses the double-end area method to compute the volume between two planes, the end areas being the horizontal areas of segmental water surfaces derived for particular increments of elevation. The area of the water surface between two cross sections at a given elevation is computed by calculating

the width of the water surface at the two stations (obtained from the cross section data) and multiplying the average of these widths by the distance between the two stations. Incremental volume is obtained by averaging the area at consecutive elevations and multiplying by the elevation increment (1 foot in this case). The areas and volumes between each set of cross sections along the centerline are accumulated to provide the complete table.

The cross section data for Fresno Reservoir included several sets of cross sections taken normal to the centerlines of several tributaries as well as the main reservoir and river.

Computation of Final Elevation-Area-Capacity Tables

The final elevation-area-capacity tables in 1-, 0.1-, and 0.01-foot elevation increments for Fresno Reservoir were generated using the Bureau of Reclamation computer program ACAP. The elevation-area data generated by Program 268 at 1-foot elevation increments were used as input to program ACAP. In ACAP, respective capacities and capacity equations are obtained by integration of the area equations defined by the input data. The initial capacity equation is tested over successive intervals to check whether it fits within an allowable error term. This one equation is used over the whole range that fits within this error term. At the next interval, a new capacity equation (integrated from the basic area equation over that interval) begins testing the fit until it too exceeds the error term. The capacity curve thus becomes a series of curves, or splines, each fitting a certain region of data. The final area equations are obtained by differentiation of the capacity equations. Capacity equations are of the form $y = a_1 + a_2x + a_3x^2$ where y is the capacity and x is the elevation above an elevation base. A sufficiently small error term was selected for this application such that the generated area and capacity values differed from the input calculated by Program 268 by less than 1 percent.

The final elevation-area values are shown in Tables 2 and 3 for 1- and 0.1-foot elevation increments, respectively. The elevation-capacity values are shown in Tables 4, and 5 for 1-, and 0.1-foot elevation increments, respectively. Areas and capacities were also computed at the 0.01-foot increments but are not included in this report. The area-capacity curves are shown on Figure 53.

SEDIMENTATION ANALYSES

Sedimentation Accumulation

Sediments have accumulated in Fresno Reservoir to a total volume of 25,665 acre-feet at elevation 2575.0 feet, top of spillway crest, since the dam was built over 38 years ago. An average annual accumulation rate of 663.2 acre-feet was computed for the period since closure (38.7 yrs). Sediments from the drainage area were deposited at a rate of 0.214 acre-foot per square mile per year.

The original elevation-area-capacity tables for Fresno Reservoir, dated 1953, are based on preconstruction (1934) data. The 1978 resurvey is the first evaluation of sediment accumulation in Fresno Reservoir. In several of the figures and tables that follow, useful comparison between the resurveyed and original reservoir is precluded by the lack of original survey data. In Figure 54 the original area-capacity curves are plotted against the 1978 resurvey curves. This plot is useful in visualizing the total loss in capacity at various elevations.

It should be noted that these sediment accumulation values are obtained from comparison with the original capacity tables. These original tables were based on areas planimetered from 5-foot interval contours. However, the original topographic maps could not be located and their accuracy or detail is unknown. Sediment samples were not taken at the time of the 1978 sediment resurvey. The absence of this data limits the conclusions that may be drawn from the available data.

There are only scattered sediment load data for the Milk River above Fresno Reservoir and accurate prediction of sediment yield is not possible. However, a memorandum from the Chief, Sedimentation Section to the Chief of the Hydrology Branch, E&R Center, dated February 21, 1968, Subject "Safety of Dams - Fresno Dam Tailwater - Milk River Project, Montana, Examination of Existing Structures" contains an estimate of 0.20 to 0.35 acre-feet per square mile annually, or approximately 550 to 1,000 acre-feet per year inflow to Fresno. The total sediment accumulation indicated in this study at elevation 2575.0 feet, spillway crest, is 25,665 acre-feet or about 663 acre-feet per year. At elevation 2580.0 feet, 0.65 feet above the maximum observed water surface, the rate is about 760 acre-feet per year. Both of these values are well within expected limits and give credence to the results.

Sediment Distribution

In Table 6, the results of the sediment distribution computations are summarized. These values show a significant sediment accumulation in the reservoir over the years, and show that a large part of the sediment is deposited in the active conservation pool (below elevation 2567.0 feet).

Figures 55 through 57 aid in describing the distribution of sediment within Fresno Reservoir. Figure 55 shows the depth-capacity relationship for Fresno Reservoir. Calculations indicate that a portion of the points fit the Type I (lake) range, a portion fit the Type II (floodplain-foothill) range, and a portion fit the Type III (hill) range. A plot of

the thalweg profile is shown on Figure 56. Without original profile data, no useful comparisons can be made. However, it appears from the data present in Table 6 that over 25 percent of the sediment has been deposited between elevations 2568.0 and 2574.0 feet (miles 10 and 12). Figure 57 shows a plot of percent depth versus percent sediment deposited. Data for the plot was taken from Table 6. The total depth was taken as the depth from the maximum observed water surface (approximately 2580.0 feet) to the streambed at the face of the dam, determined from the 1978 resurvey. As may be seen from Table 6, the sediment distribution is fairly uniform, with the greatest accumulation in the active conservation pool. The accumulation in the upper, or active, part of the reservoir is explained by observing the cross sections in this portion of the reservoir. Although the reservoir is narrow in relation to its length, the increase in cross sectional area in this region is sufficient to reduce inflow velocity and allow sediment deposition. The lower portion of the reservoir may be less impaired because of the high accumulation rate in the upper portion of the reservoir and may benefit from a slight flushing action near the outlet works.

Reservoir Sedimentation Summary

A summary of the reservoir sediment data for the 1978 survey is contained in Table 7. The data include a tabulation of incremental sediment inflow volume and sediment accumulation computed for the periods between 1939 (original) and the 1978 resurvey. These data and other information in the table are valuable for future surveys and other reservoir sediment investigations. The capacity of Fresno Reservoir at elevation 2575.0, the top of the joint use space, is 103,397 acre-feet. This is approximately 20 percent less (25,665 acre-feet) than the original capacity. The area at this elevation is 4,878 acres, a reduction of about 15 percent (897 acres) from the original area. Table 8, Reservoir Capacity Allocations, shows the allocations of the storage space in Fresno Reservoir as a result of the 1978 resurvey.
